Received May 18, 2000; revised August 7, 2000; published online December 19, 2000

Nucleotide sequences for the complete mitochondrial control region (1158 bp) were used to determine the phylogenetic relationships among populations of the yellow mud turtle, *Kinosternon flavescens* (Kinosternidae). Phylogenetic analysis of the mtDNA sequences reveals a polyphyletic *K. flavescens* with three distinct clades: (1) *K. flavescens* of the Central Plains, including isolated populations of Illinois and Iowa, (2) *K. arizonense* in the Sonoran Desert of Arizona and Mexico, and (3) *K. durangoense* in the Chihuahuan Desert of Durango, Coahuila, and Chihuahua, Mexico. Sequence divergence and nucleotide diversity calculations support a hypothesis of Great Plains *K. flavescens* dispersal and subsequent isolation of populations in the Midwest related to climatic change during the Pleistocene. © 2001 Academic Press

Key Words: Kinosternidae; *Kinosternon flavescens*; mtDNA; control region; Pliocene; Pleistocene.

INTRODUCTION

The genetic and geographic structure of a species is dictated by current ecology and historical patterns of dispersal and vicariance. Intraspecific phylogenetics attempts to describe population structure and the processes of evolution responsible for this structure by assessing the degree of concordance between geographic location of haplotypes and their position in an inferred gene genealogy. Erroneous estimates of phylogeny may occur when morphological characters that represent phenotypic adaptations to specific environmental conditions and that do not reflect evolutionary history are used (Avise, 1986). For example, there have been three attempts to describe the geographic variation in the yellow mud turtle, *Kinosternon flavescens*, but all have been limited by the small number of variable, quantitative, morphological characters possessed

by the species (Iverson, 1979; Houseal *et al.*, 1982; Berry and Berry, 1984).

The yellow mud turtle is a small, semiaquatic turtle that is widely distributed from central Illinois west to Nebraska and south to Sonora and the state of Durango, Mexico (Iverson, 1979). Historically, four subspecies of *K. flavescens* have been recognized: *K. f. flavescens* (Agassiz, 1857), *K. f. arizonense* Gilmore (1922), *K. f. spooneri* Smith (1951), and *K. f. durangoense* Iverson (1979). These designations were based, in part, on the disjunct distribution of *K. flavescens* (Iverson, 1979; Fig. 1). The species typically is found in well-draining soils of desert and grassland habitats. Individual *K. flavescens* exhibit high fidelity to migration paths between feeding ponds and estivation/hibernation sites (Iverson, 1991a). Life history characteristics such as site fidelity and low vagility, enforced by drainage limits and a disjunct distribution, allow the prediction that differentiation among populations of *K. flavescens* will be correlated with geographic distance.

Previous systematic studies of *K. flavescens* focused primarily on skin or shell coloration and ratios of shell measurement characters (Iverson, 1979; Houseal *et al.*, 1982; Berry and Berry, 1984). These characters allowed the recognition of the subspecies *K. f. durangoense* and supported the distinctiveness of *K. f. arizonense* (Iverson, 1979), but also resulted in differing conclusions regarding the taxonomic status of *K. f. spooneri* (Iverson, 1979; Houseal *et al.*, 1982; Berry and Berry, 1984). Conflicting results from previous studies indicate that additional data are needed to address intraspecific relationships among populations of *K. flavescens*. Analysis of mtDNA haplotypes offers an opportunity to examine the phylogenetic component of intraspecific differentiation of a species with limited morphological variation. Such a molecular data set would also be applicable to a phylogenetic analysis, rather than being limited to the phenetic methodologies used previously.

The goal of this study was to develop a phylogenetic hypothesis for *K. flavescens* populations, addressing questions of subspecific status and evidence for vicari-

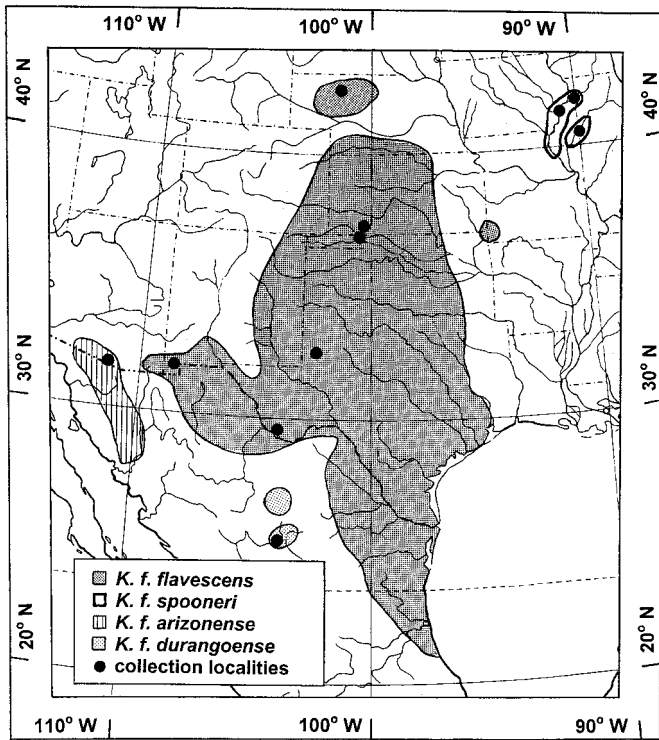

FIG. 1. Distribution map of the four currently recognized subspecies of *Kinosternon flavescens*. Location of specimens examined are indicated by dots.

ant or dispersal events using a molecular data set. For example, disjunct populations of *K. flavescens* in Illinois, Iowa, and Missouri may represent the dispersal of individuals from the Great Plains during extension of the prairie into the Midwest during the Xerothermic Interval of the Pleistocene (Smith, 1957). These populations then may have been isolated in well-drained, sandy soil habitats after a climatic shift resulting in a mesic environment occurred. In areas where geographic isolation mechanisms may not be as evident, congruent biogeographic patterns among unrelated groups can provide evidence for a broad vicariant event (Cracraft, 1982; Avise and Ball, 1990). Although there has not been a proposed mechanism that isolated the Sonoran and the Chihuahuan desert populations of *K. flavescens*, examination of phylogenetic relationship and geological history may provide an explanation for the observed pattern of endemism.

Because previous genetic studies have indicated a slower evolutionary rate in turtle mtDNA than in that of other vertebrates (Avise *et al.*, 1992), the mitochondrial control region (CR) was chosen based on the rapid evolutionary rate reported for this gene (Upholt and Dawid, 1977; Aquadro and Greenberg, 1983; Chang and Clayton, 1985). Because the control region accumulates base substitutions, additions, and deletions quickly, it has been used successfully for phylogenetic

analysis of species with low genetic variability due to recent divergence or reduced microevolutionary rate (Avise *et al.*, 1992; Bernatchez *et al.*, 1992; Baker and Marshall, 1997; Good *et al.*, 1997; Lamb and Osentoski, 1997; Parker and Kornfield, 1997; Walker *et al.*, 1998).

Phylogenetic studies of turtles using control region sequences have been restricted to the 5' end adjacent to the proline tRNA (Lamb *et al.*, 1994; Osentoski and Lamb, 1995; Encalada *et al.*, 1996; Lamb and Osentoski, 1997; Walker *et al.*, 1998, 1995; Walker and Avise, 1998; Roman *et al.*, 1999). This portion of the control region has provided some resolution in terms of genotypic variants and intraspecific phylogeography (Encalada *et al.*, 1996) and species/clade identification (Lamb *et al.*, 1994). Herein, we present complete control region sequences that we believe strengthen the argument for position homology and increase the number of informative characters in the data set.

MATERIALS AND METHODS

The sampling scheme was designed to assay intraspecific variability across the wide range of *K. flavescens*, including all subspecies and extant isolated populations (Table 1, Fig. 1). Seven populations of *K. f. flavescens* and three populations of *K. f. spooneri* were represented. Two individuals from each of the narrowly distributed subspecies, *K. f. arizonense* and *K. f. durangoense*, were also included. *Kinosternon baurii*, *K. hirtipes*, *K. subrubrum*, and *Sternotherus odoratus* were chosen as outgroup taxa in the phylogenetic analysis based on hypotheses of molecular (Seidel *et al.*, 1986; Starkey, 1997; Iverson, 1998) and morphological (Iverson, 1991b) character analyses of the Kinosternidae.

Total DNA was extracted from frozen whole blood, packed blood cells separated from plasma, or muscle and liver tissues. Blood samples from state-protected *K. f. spooneri* were collected from the dorsal cervical sinus as described by Bennett (1986). Tissues were homogenized on ice in STE buffer (10 mM Tris-HCl, pH 7.5, 10 mM NaCl, 1 mM EDTA) and digested at 50°C after the addition of 50 μ l of 20% SDS and 20 μ l of 10 mg/ml proteinase K. The supernatant was extracted with buffered phenol (pH 8.0) and chloroform/isoamyl (24:1). Nucleic acids were precipitated overnight (-20°C) with 50 μ l of 3 M NaOAc and 1.0 ml of absolute ethanol. For problematic blood samples with low DNA yields, an alternative isolation protocol was used (Bickham *et al.*, 1996).

An 1170-bp region containing the complete control region and flanking proline and phenylalanine tRNAs was amplified as a single fragment in a 50- μ l polymerase chain reaction (PCR) using primers ChelProF (5'-CCGGTCCCCAAAACCGGAAC-3') designed by Allard *et al.* (1994) and 12S-57R (5'-GATACTTGCATGTGTAAGTTT-3') located within the conserved 5' end of the

12S rRNA. The latter primer was designed by aligning sequences from *Homo*, *Xenopus*, *Trachemys*, and multiple fish taxa available on GenBank. Double-stranded PCRs contained 2.5 mM MgCl₂, 0.25 mM each deoxynucleotide, 0.5 mM each primer, and 2.5 units *Thermus aquaticus* DNA polymerase (Promega). Double-stranded amplification used the following conditions: initial denaturation for 5 min at 94°C and then 30 cycles of denaturation (94°C, 30 s), annealing (45–53°C, 30 s), and extension (72°C, 90 s). PCR products were run on 2% low-melt (65°C) NuSieve GTG agarose (BMA BioProducts) in 1× TAE running buffer. The target fragment was gel-isolated and purified following the protocol for Wizard PCR preps DNA purification system (Promega). PCR products that were not gel-isolated were purified using spin filtration columns (Millipore ultra-free-mc No. UFC3 LTK00).

Purified PCR products were ligated into pGEM-T vector plasmids (Promega) and transformed into DH5 alpha-*Escherichia coli* competent cells. Plasmids from positive colonies were isolated by alkaline lysis (PerfectPrep kit; 5 Prime-3 Prime Inc.) and used as templates in DNA sequencing reactions. The forward and reverse strands were sequenced from two separate clones for each specimen. A third clone was used to resolve any ambiguities. Chain-termination cycle sequencing was performed using the Delta-*Taq* Cycle Sequencing Kit (Amersham United States Biochemical, Cleveland, OH) or the fmol DNA Sequencing Kit

(Promega). Internal primers were designed from sequence alignments (Table 2). Sequencing products were separated by electrophoresis through 6% polyacrylamide/8.3 M urea gels (SequaGel Sequencing System, National Diagnostics) and visualized by autoradiography.

Autoradiographs were read manually as data files in the program EasyReader (Hitachi Software Engineering). Complete double-stranded sequences were then assembled by overlapping sequence files in Sequencher (Gene Codes, Ann Arbor, MI). Nucleotide sequence data for 14 *K. flavescens* and the 4 outgroup taxa were aligned in Clustal W (Thompson *et al.*, 1994). The control region alignment (including gaps) of 18 taxa allowed the identification of some conserved elements: F-box, CSB1, and three domains of the control region

that have been found among highly divergent taxa (Southern *et al.*, 1988; Saccone *et al.*, 1991; Baker and Marshall, 1997; Zink and Blackwell, 1998a) (see Appendix). Using the criteria of Zink and Blackwell (1998a), domains were defined by the positioning of the F-box and CSB1 and the degree of base pair conservation. Domain I begins at origin of the CR and is terminated at the beginning of the F-box. Domain II is the central conserved region. Domain III begins at the origin of the CSB1, terminates at the phenylalanine tRNA, and is the most variable region. Regions of ambiguity in Domain III were removed from the final analysis. NBRF/PIR files were imported into PAUP* vers. 4.0b2 (Swofford, 1998) for phylogenetic analyses.

Both character-state and distance-based methods were used to estimate phylogenetic relationships within *K. flavescens*. All maximum-parsimony (MP) analyses employed a branch and bound search of the equal weighted data, and character states inferred as gaps were treated as missing data. Only minimum-length trees were retained and zero-length branches were collapsed. Bootstrap support for each node was determined using 2000 replications of a fast heuristic search available in PAUP*. Robustness of clades was also assessed using decay index values (Bremer, 1994), which calculate the number of additional steps needed to collapse nodes in the minimum-length tree using AutoDecay vers. 3.0 (Eriksson and Wikstrom, 1995). Phylogenetic signal was assessed in the aligned control region data set using the g_1 statistic (Hillis and Huelsenbeck, 1992). Tests for phylogenetic signal were conducted using the complete control region and each of the three domains separately. Phylogenetic hypotheses were also generated via the neighbor-joining (NJ) algorithm (Saitou and Nei, 1987), using the Kimura two-parameter distance correction (Kimura, 1980). Alternative topologies to test the monophyly of *K. flavescens* were constructed as constraint trees in MacClade vers. 3.07 (Madison and Madison, 1992). The modified Templeton test (Templeton, 1983a,b; Felsenstein, 1985), which is based on the Wilcoxon sign-ranks test, was used to examine the statistical significance of the shortest tree length (most-parsimonious tree) relative to the alternative hypotheses. Tests were conducted in PAUP*, which incorporates a correction for tied ranks.

An effort was also made to compare *K. flavescens* sequences from this study to other kinosternid taxa. Although sequence data from *Sternotherus minor* and *S. odoratus* were unavailable on GenBank, we were able to compare *K. flavescens* to these taxa using Nei's equation 10.4 (Nei, 1987) of nucleotide (nt) diversity. Nt diversity has been calculated for *S. minor* and *S. odoratus* from partial control region sequence data (Walker *et al.*, 1995) and restriction site analysis of mtDNA (Walker *et al.*, 1997), respectively. By reducing the *K. flavescens* sequence data to the first 432 bp (= reduced data set), we were able to calculate nt diversity

from the pairwise comparisons (Table 4) and compare it to Walker *et al.*'s estimations. Nt diversity was calculated for the *K. flavescens* species group and subgroups as defined by the recovered clades in MP and NJ analyses and current taxonomy.

RESULTS

The complete control region alignment for all 18 specimens contained 1158 base positions and exhibited 224 variable sites, 113 of which were phylogenetically informative under maximum-parsimony criteria. All mitochondrial control region sequences were aligned unambiguously for Domains I and II, with only a few single-base insertion/deletion events (indels) required. In Domain III, indels were more frequent and of varying lengths in relation to the AT repeat. The largest insertion/deletion event occurred in Domain III of the *S. odoratus* sequence, where a 22-bp insertion began at position 884, upstream from the AT repeat, and was succeeded by two shorter, nonrepetitive insertions. Ambiguous alignment of the large AT repeat (base positions 957–1034) required that we omit it from the analysis. This omission resulted in a data set consisting of 1082 base positions and exhibiting 193 variable sites, 97 of which were phylogenetically informative. The omission did not change the resulting topologies. Strong phylogenetic signal was detected for the control region data set (g_1 statistic = -0.796 ; $P < 0.01$).

Parsimony analysis for 18 taxa yielded 16 most-parsimonious trees of 269 steps, with a consistency index excluding uninformative characters of 0.682 (Fig. 2). Preliminary parsimony analyses had shown that the ingroup was nonmonophyletic with respect to the outgroup taxa, *K. baurii*, *K. hirtipes*, *K. subrubrum*, and *S. odoratus*. In subsequent analyses we designated *S. odoratus* as the outgroup and *K. baurii*, *K. hirtipes*, and *K. subrubrum* as functional outgroups based on previous molecular hypotheses of the Kinosternidae (Starkley, 1997; Iverson, 1998). *K. flavescens* was determined to be polyphyletic using the algorithm suggested by Farris (1974). Populations of *K. flavescens* formed two main clades, *K. f. flavescens* + *K. f. spooneri* and *K. f. arizonense* + *K. f. durangoense*. A clade composed of *K. baurii* and *K. subrubrum* was the sister group to the *K. f. flavescens* + *K. f. spooneri* clade. Variation among the 16 most-parsimonious tree topologies was restricted to the placement of the southwestern United States (New Mexico and Texas) populations of *K. f. flavescens* and relationships among the Great Plains/Midwest populations of *K. f. flavescens* and *K. f. spooneri*. Decay index values for internal branches ranged from 0 to 12 steps (Fig. 2).

The distance analysis using the NJ algorithm with the Kimura two-parameter distance measure resulted in a topology similar to that shown by MP (Fig. 3). Groups supported by bootstrap values >95% on the distance tree included all groups recovered as >95% in

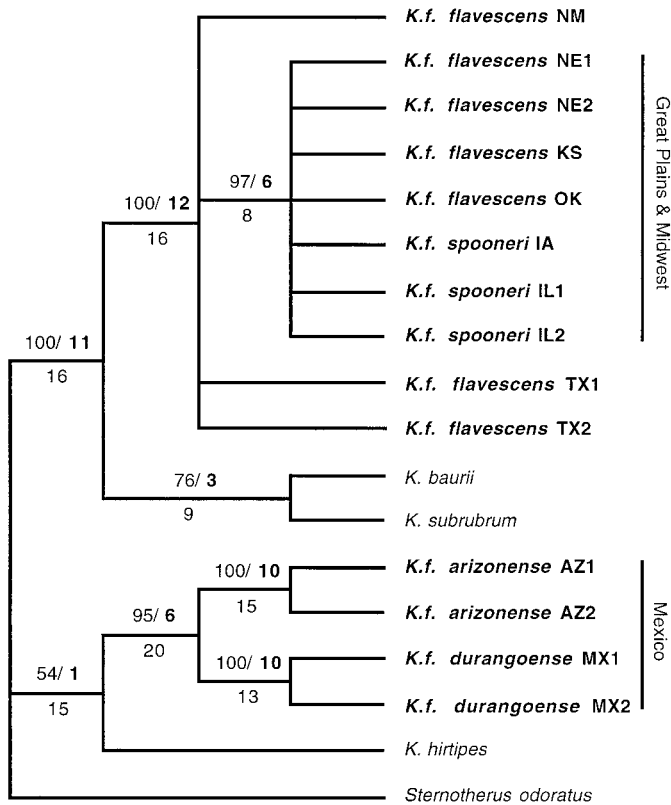

FIG. 2. Strict consensus tree of the 16 most-parsimonious trees (TL = 269; C.I. = 0.799; R.C. = 0.682) recovered in maximum-parsimony analysis of control region (omitting AT repeat). Bootstrap (2000 replications) and decay index values (in boldface) are indicated above branches. Character support is given below branches.

the MP analysis. The only exception was support in the NJ topology of a southwestern (New Mexico + Texas) *K. f. flavescens* clade.

To examine the nonmonophyly of *K. flavescens*, an alternative phylogenetic hypothesis was constructed in MacClade (Maddison and Maddison, 1992) by constraining the monophyly of the previously recognized *K. flavescens*. The new constraint topology was 18 steps longer and significantly different ($P < 0.0015$) from that of the most-parsimonious trees, which supports a nonmonophyletic *K. flavescens*.

Significant phylogenetic signal was detected in all three control region domains using 10^5 randomly generated trees (Table 3). Domain I contained 303 base positions with 68 variable positions; 42 were phylogenetically informative (g_1 statistic = -0.775 ; $P < 0.01$). Domain II contained 355 base positions with 40 variable sites; 16 were phylogenetically informative (g_1 statistic = -0.952 ; $P < 0.01$). Domain III contained 500 base positions with 116 variable positions; 55 were phylogenetically informative (g_1 statistic = -0.711 ; $P < 0.01$).

Within the currently recognized *K. flavescens*, nt diversity was widely variable (Tables 4 and 5). Pairwise

nt diversity among all *K. flavescens* averaged 0.039 (3.9%), ranging from 0 to 0.085 (8.5%). When excluding *K. f. arizonense* and *K. f. durangoense*, the nt diversity was drastically reduced to 0.006 (less than 1%). Average nt diversity between *K. f. spooneri* and the nominate subspecies was 0.005 (0.5%). Average nt diversity between *K. f. arizonense* and *K. f. durangoense* was 0.015 (1.5%), much higher than that seen within *K. f. flavescens* + *K. f. spooneri*. The comparison between *K. f. flavescens* + *K. f. spooneri* and the Mexican subspecies averaged 0.080 (8.0%).

DISCUSSION

Significant phylogenetic signal was found in all three domains of the control region using the g_1 statistic, suggesting that Domain III may be as important in generating an accurate phylogeny of closely related taxa as the more commonly used Domains I and II

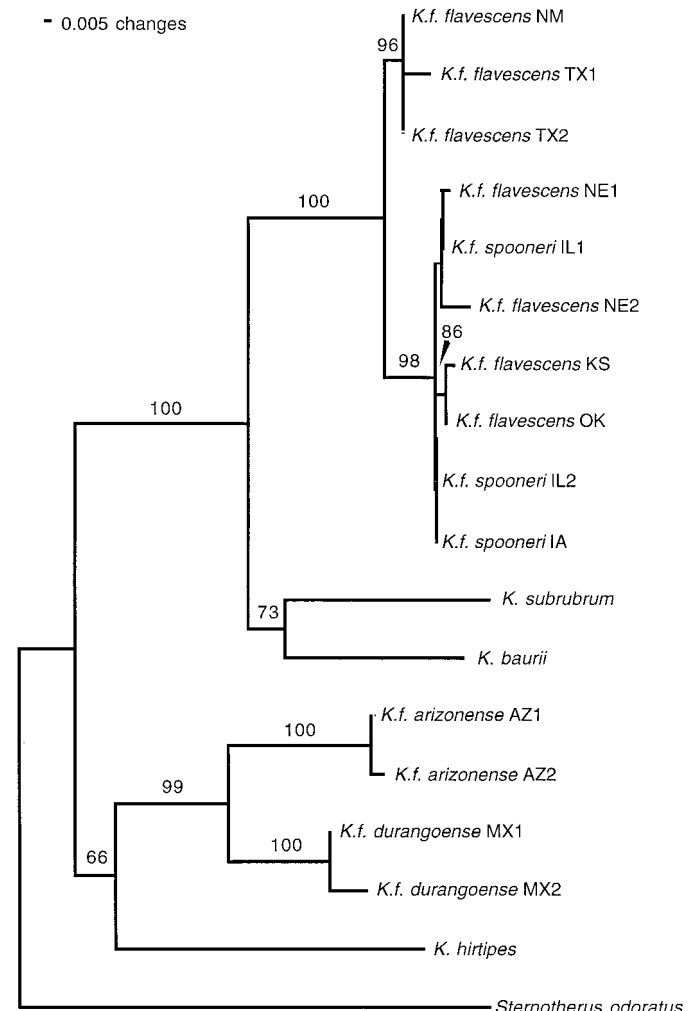

FIG. 3. Neighbor-joining tree using the Kimura two-parameter distance correction. Bootstrap values (>50%) from 2000 replications are indicated above branches.

TABLE 3

Distribution of Phylogenetically Informative and Variable Positions in the Complete CR and Its Three Domains

	g_1	Significance	Total positions	Variable positions	Phylogenetically informative sites
Complete CR ^a	-0.796	$P < 0.01$	1080	193	97

Domain II	-0.952	$P < 0.01$	355	40	16
Domain III	-0.711	$P < 0.01$	500	116	55

^a Omitting AT repeat (957–1036 bp).

(Table 3). For turtles, phylogenetic analyses have been performed using only the 5' end (Domain I and partial Domain II) of the control region (Encalada *et al.*, 1996; Lamb *et al.*, 1997, 1994; Walker *et al.*, 1998, 1995; Roman *et al.*, 1999). It should be noted that when our data set was limited to this portion, some relationships were altered and overall branch support was reduced (J. M. Serb, unpublished). Although it is intuitive that a complete gene will generally provide more phylogenetically informative characters than a partial gene, we suggest that the potential utility of the control region has not been fully exploited.

Low Nucleotide Diversity among Central Plains K. flavescens Populations

Central Plains populations (*K. f. flavescens* + *K. f. spooneri*) have greatly reduced nt diversity (0.06%) compared to *S. minor* (1.7%) or *S. odoratus* (1.6%) (Walker *et al.*, 1995, 1997; respectively). The low nt diversity recovered among Central Plains populations can be explained by the species' natural history. *K. flavescens* inhabits xeric environments with unstable conditions, is more terrestrial (Iverson, 1991a), often

migrating between bodies of water (Cope, 1892), and tends to have a large activity range (Mahmoud, 1969) compared to other kinosternid species, such as *S. odoratus*, which is more restricted to aquatic environments. In addition, genetic differentiation among populations will be slowed considerably by migration, and even infrequent migration is enough to prevent any appreciable genetic differentiation unless strong differential selection exists (Eq. 9.65 in Nei, 1987). An increase in the probability of contact among populations resulting from large activity ranges and dispersal due to unpredictable environmental conditions supports the molecular findings of relatively low nt divergence in Central Plains *K. flavescens*, even compared to the widely distributed species, *S. odoratus* (Walker *et al.*, 1997).

Pleistocene Isolation of K. f. spooneri Populations

Nucleotide diversity was also extremely low between the isolated *K. f. spooneri* populations and the nominate subspecies (Table 5). Although the sample size was small, six individuals (all *K. f. spooneri* and *K. f. flavescens* NE1, Kansas and Oklahoma) possessed the same haplotype, suggesting that the time of isolation

TABLE 5

Estimated Nucleotide Diversity (π^a) within Kinosternidae Taxa Using Reduced and Complete Data Sets of the Control Region

	Mean π (reduced CR)	Min	Max	Mean π (complete CR)
<i>K. flavescens</i> (all)	0.039	0	0.085	0.035
<i>K. flavescens</i> (Central Plains)	0.006	0	0.016	0.006
<i>K. f. flavescens</i> vs <i>K. f. spooneri</i>	0.005	0	0.014	0.005
<i>K. flavescens</i> (Central Plains) vs Mexican subspecies	0.080	0.073	0.085	0.071
<i>K. f. arizonense</i> vs <i>K. f. durangoense</i>	0.015	0.002	0.024	0.020
<i>S. minor</i> ^b	0.017	0.002	0.032	—
<i>S. odoratus</i> ^c	0.016	—	0.031	—

^a Mean $\pi = [n(n - 1)](\sum f_i f_j \pi_{ij})$, where f_i and f_j are the frequencies of the i th and j th haplotypes in a sample size of n , and π_{ij} is the uncorrected estimate of sequence divergence between the i th and j th sequences (Nei, 1987).

^b Walker *et al.* (1995).

^c Walker *et al.* (1997).

between the Great Plains and the Midwest may have been too recent for fixed mutations to accumulate in the control region. Geological evidence supports a recent isolation event. Fossils of *K. flavescens* are known from the Hemphillian (Late Miocene/Early Pliocene) (Parmley, 1992) from Nebraska, which was not covered by the maximum extent of glaciation (Nebraskan and Kansan advances), unlike Iowa and the majority of Illinois. It has been hypothesized that these populations of *K. flavescens* persisted in a refugium in the Sand Hills of Nebraska during the glacial advances and became the founders of Midwestern populations during the expansion of the Prairie Peninsula.

A description of the postglacial climate change of the Midwest is given by Wright (1968). An accelerated climate change occurred 10,000–11,000 years ago as a result of the final retreat of the Wisconsinian ice sheet from the Great Lakes region. Boreal vegetation on the periphery of the retreating glacier was replaced by deciduous taxa that were gradually dominated by more xeric species (i.e., *Quercus* spp.) around 8000 years ago. By 7000 years ago, the Midwest had reached a maximum of warmth and dryness (Xerothermic Interval), allowing prairie grassland species from the west to dominate. After this peak of prairie expansion from the Great Plains into Illinois and Indiana (known as the Prairie Peninsula), a slow reversal in the climatic trend occurred. The climate cooled and annual precipitation increased more rapidly, creating a mesic environment by 4000 years ago. The xeric-adapted taxa that had invaded from the west during the Xerother-

mic Interval were either eliminated or restricted to well-drained, sandy soils (see Smith, 1957). Thus, the history of the Prairie Peninsula suggests that the time of isolation between *K. f. spooneri* and the nominate subspecies was only about 4000 years ago. The recent isolation event in conjunction with a seemingly slower evolutionary rate in turtle mtDNA (Avise *et al.*, 1992) would predict an unresolved polytomy and an undiagnosable *K. f. spooneri* subspecies, as was recovered in this study.

Differentiation of Mexican Subspecies

Molecular evidence strongly supports a distinct clade of *K. f. arizonense* and *K. f. durangoense*. These subspecies were separated from other *K. flavescens* by long branches, robust bootstrap support, relatively high decay index values, and many synapomorphies (Fig. 2). Indeed, the nt diversity between Mexican and Central Plains subspecies (7.3%) is more than four times the diversity calculated across populations of other wide-ranging kinosternids that have been studied (Table 5). These results clearly support our finding that *K. flavescens*, as previously recognized, is an unnatural group.

In addition to mitochondrial evidence, morphological and life history traits support the distinction of the Mexican subspecies. In previous morphometric analyses, *K. f. arizonense* and *K. f. durangoense* were consistently distinct from all other populations of *K. flavescens* and from each other (Iverson, 1979; Houseal *et al.*, 1982; Berry and Berry, 1984). Furthermore, morphological separation has been observed in skeletal to body mass ratios (Iverson, 1989). *K. f. arizonense* and *K. f. flavescens* also differ in numerous life history traits, including timing of the reproductive cycle, number of clutches per year, and the average percentage of gravid female body mass incorporated into the clutch of eggs (Iverson, 1989). Iverson (1989) has also shown that activity periods and reproductive cycles of *K. f. arizonense* are asynchronous with those of the nominate subspecies, and similar observations have been made for *K. f. durangoense* (J. B. Iverson, unpublished data). Environmental cues for activity periods also differ between *K. f. arizonense* and Central Plains *K. flavescens*; precipitation stimulates Mexican desert populations, whereas the gradual spring warming seems to be the stimulus for *K. f. flavescens* (Iverson, 1989). Incongruent activity periods suggest temporal as well as geographic isolation between Mexican and Central Plains populations.

Nucleotide diversity between *K. f. arizonense* and *K. f. durangoense* was estimated at 1.5%, higher than estimates across the range of Central Plains *K. flavescens* (Table 5). Geographically, the two Mexican taxa are isolated from each other by the Continental Divide, which also separates the closely related *K. hirtipes* and *K. sonoriense* (Iverson, 1981). Similar zoogeographic

patterns have been recovered in phylogenetically unrelated groups such as scaled quail (*Callipepla*; Zink and Blackwell, 1998b) and pocket mice (*Chaetodipus*; Riddle, 1995), supporting gene–geography concordance described by Cracraft (1982) and Avise and Ball (1990). Congruent zoogeographic patterns in the *K. flavescens* phylogeny, concordant with *Callipepla* and *Chaetodipus* phylogenies, implies an historical vicariant event which affected many different taxa.

The Continental Divide consists of the Sierra Madre Occidental and the Colorado Plateau, which forms a barrier between the Chihuahuan and the Sonoran deserts. Historically, the Cochise Filter Barrier, a 100- to 200-km-wide gap between these mountain ranges, has been the only physiographic portal along the western wall of the Chihuahuan desert (Morafka, 1977). Between events of orogenesis, this portal may have periodically provided an east–west route for gene flow between the two deserts during the Pliocene or Pleistocene (Morafka, 1977). Mammalian data (see Riddle, 1995) suggest that the isolation of the Sonoran and Chihuahuan deserts may have occurred over a single broad period or several events of the Late Miocene (Hemphillian) through the Pliocene (Blancan) during the secondary uplift of the Sierra Madre Occidental. Based on the fossil evidence of morphologically modern *K. f. arizonense* from the Late Pliocene (Blancan) (Gilmore, 1922), we favor either the secondary uplift of the modern Sierra Madre Occidental during the Miocene (Cohn, 1965) or the closing of the Cochise Filter Barrier during the Late Miocene/Early Pliocene as the event isolating the Sonoran and Chihuahuan *K. arizonense*–*K. durangoense* populations.

(de Queiroz and Donoghue, 1990). The molecular data support the recognition of three distinct species within *K. flavescens*: (1) *K. flavescens* of the Central Plains, including populations of the Illinois and Mississippi River drainages of Illinois, Iowa, and Missouri; (2) *K. arizonense* in the Sonoran Desert of Arizona and Mexico; and (3) *K. durangoense* in the Chihuahuan Desert of Durango, Coahuila, and Chihuahua, Mexico. Geographic isolation and differences in morphological and life history traits lend further support for these designations. Although the recognition of *K. f. spooneri* (as previously defined) is not supported using mitochondrial control region sequences, further study of phylogeography within *K. flavescens* (*sensu stricto*) may demonstrate variation that is worthy of subspecific designation. Finally, the phylogenetic placement of *K. arizonense* and *K. durangoense* within the Kinosternidae was not fully resolved in this study and will require further analysis including additional Mexican species. Once those phylogenetic relationships are clarified, hypotheses of speciation events can be investigated in a geological context.

CONCLUSIONS: TAXONOMIC SUGGESTIONS FOR *K. flavescens* SUBSPECIES

Because sequences of the complete mitochondrial control region recovered a polyphyletic *K. flavescens*, the current taxonomic arrangement of its subspecies is not supported. We chose to recognize taxa using the monophyly version of the Phylogenetic Species Concept

ACKNOWLEDGMENTS

This research was submitted in partial fulfillment of requirements for the M.S. degree for the senior author (J.M.S.) in the Department of Natural Resources and Environmental Sciences, University of Illinois Champaign–Urbana. Tissue specimens of *K. flavescens* from Texas and Iowa were provided by A. H. Price and J. L. Christiansen, respectively. Collection of tissues of *K. durangoense* in Mexico was facilitated by J. Lemos-Espinal and G. R. Smith. J. Palis provided the specimen of *K. subrubrum*. D. Walker provided information regarding nucleotide diversity calculations. We thank C. Lydeard, M. A. Pollock, K. J. Roe, and two anonymous reviewers for helpful and constructive comments. We also thank T. J. Near for technical assistance and D. A. Neely for the distribution map illustration. This work was supported in part by the Theodore Roosevelt Memorial Fund of the American Museum of Natural History, the Helen T. and Frederick M. Gaige Award of the American Society of Ichthyologists and Herpetologists, the Herbert Holdworth Ross Memorial Grant of the Illinois Natural History Survey, and a grant from the Illinois Endangered Species Protection Board.
